Abstract

This paper describes the synthesis of highly branched gold nanoparticles through a facile seeded growth approach using poly(allylamine hydrochloride) (PAH) as shape inducing agent. The obtained branched Au NPs present highly tunable optical properties in the Vis-NIR region from ca. 560 nm to 1260 nm. We controlled the morphology, and therefore the
optical response, of the NPs by either changing the gold salt to seed ratio or the fine-tuning of the solution pH. We proposed that the formation of size-dependent PAH-AuCl₄⁻ aggregates as demonstrated by dynamic light scattering measurements, together with pH-dependent gold salt speciation might be responsible for the branched morphology. Advanced electron microscopy techniques demonstrated the polycrystalline nature of the NPs and facilitated a better understanding of branched morphology. Additionally, the refractive index sensitivity estimated by the inflection point of the Localized Surface Plasmon Resonance (LSPR) band can be controlled by tuning the nanoparticle branching. Furthermore, the versatility of the PAH chemistry allowed the easy functionalization of the synthesized NPs.

1. Introduction

Since the controlled synthesis of anisotropic gold nanoparticles (AuNPs) became feasible,¹ this class of AuNPs has been rapidly put to use in many different scientific fields for optical,²,³ biomedical,⁴,⁵ and catalytic⁶ applications. The main asset of anisotropic AuNPs is that the Localized Surface Resonance Plasmon (LSRP) band can be tuned “on-demand” through the tight control of the nanoparticle (NP) shape and size, which give rise to new and exciting physicochemical properties.⁷ For instance, unlike the optical signature of gold spherical NPs, which tends to cover a relatively small wavelength range according to the NP diameter, plasmon resonances of gold nanorods can be controlled in an expanded wavelength range from visible to the near-infrared region of the spectrum, by varying the aspect ratio of the nanoparticle.³ Nowadays, alongside nanorods there is an extensive library of anisotropic AuNPs available. Thus, the synthesis and characterization of anisotropic branched or star-shaped AuNPs NPs have been the focus of many studies in the last decade. The optical
properties of branched/star-shaped AuNPs are characterized by an intense LSPR band which can be tuned from 600 to 1200 nm (mainly as a function of the tip length, thickness and angle, but also the core size) and less intense band in the 500-600 region associated with the AuNP core.\textsuperscript{3} Importantly, branched AuNPs can offer a considerable electromagnetic field enhancement (even superior to Au nanorods) located at the tips.\textsuperscript{3} These attractive optoelectronic properties have been readily adopted in applications ranging from advanced optical sensors\textsuperscript{8} to nanomedical tools.\textsuperscript{4,9} Branched NPs that offer control over the optical properties in a wide range of wavelengths are mostly obtained through a seed-mediated strategy in the presence of a shape-inducing agent such as surfactants (cetyltrimethylammonium bromide, CTABr,\textsuperscript{10} and zwitterionic lauryl sulfobetaine, LSB,\textsuperscript{11} or Triton X\textsuperscript{12,13}), polymers (polyvinylpirrolidone, PVP\textsuperscript{14,15}), Good’s buffers,\textsuperscript{16} or even silver ions in a surfactant-free solution.\textsuperscript{17,18}

Although these branched AuNPs are promising candidates for optical or biomedical applications, post-functionalization steps are essential to impart stability as well as functionality to the as-synthesized NP.\textsuperscript{19,20} Unfortunately, the gold surfaces located at the tips possess a high density of low-coordinated atoms being a high surface energy, which could promote the reshaping of the NPs upon surface functionalization, thus altering their optical properties.\textsuperscript{20} In order to prevent any reshaping process, surface modification with different thiol derivatives has been proposed.\textsuperscript{19}

The development of novel synthetic routes for the synthesis of branched AuNPs with tunable optical properties using functionalizable shape-inducing agents has been identified as a challenging approach. For instance, polyallylamine hydrochloride (PAH), a positively charged polyelectrolyte with a high degree of primary amine functions and excellent hydrophilic properties, has shown potential as a shape-directing agent in the synthesis of
anisotropic noble metal NPs (such as platinum or copper),\textsuperscript{21,22} or as a stabilizing and reducing precursor in the synthesis of small spherical AuNPs.\textsuperscript{23,24} Additionally, Tang and coworkers reported a one-pot synthesis of branched AuNPs using PAH as a shape-inducing and capping agent after reduction with ascorbic acid (AA).\textsuperscript{25} The obtained dendritic structures, named nanocorals, showed excellent electrocatalytic activity in ethanol oxidation, but the optical properties were not reported. Interestingly, the amine functionalities of the PAH allow its post-functionalization through either electrostatic interaction\textsuperscript{26,27} or carbodiimide chemistry.\textsuperscript{27,28}

Taking into consideration these previous works, we developed a seed-mediated approach for the synthesis of branched AuNPs assisted by PAH. The strategy relies on the prevention of nucleation events while promoting the growth process through the presence of small Au seeds. The careful control of the experimental conditions allows obtaining branched AuNPs with highly tunable optical properties (\textit{ca.} 560-1260 nm). High-resolution transmission electron microscopy (HR-TEM) in combination with scanning transmission electron microscopy (STEM) tomography reveals a polycrystalline structure and an intricate morphology. Furthermore, the refractive index sensitivity estimated by the inflection point of the Localized Surface Plasmon resonance band can be easily controlled by tuning the nanoparticle branching. Additionally, taking advantage of the surface-exposed amine groups, the branched AuNPs could be easily functionalized with polyacrylic acid-co-maleic acid (PAcMA) via carbodiimide chemistry without affecting their optical properties.

2. Experimental. Results and discussion
Polyallylamine hydrochloride (PAH) is a cationic polyelectrolyte with a weak-base character. Recently, Tang et al. reported the one-pot synthesis of branched Au nanocorals where the polyallylamine hydrochloride (PAH) acted as capping and shape control agent and ascorbic acid as reducing agent. Nevertheless, the optical properties of the so-called Au nanocoral were not analyzed and no attempts to control the particle size or to study the influence of the pH were performed. The latter is especially interesting considering that the redox potential of ascorbic acid, Au salt speciation and the degree of ionization in PAH molecules are pH-dependent, which could affect the formation kinetics of Au nanoparticles as well as the interaction of PAH through the amine groups with the gold salt and the surface of AuNP.

Here, we employed a seeded-growth methodology to fully understand the key parameters affecting the synthesis of branched Au NPs and aiming their size and shape control. Thus, citrate-stabilized gold nanoparticles with an average size of 3-5 nm, synthesized via the fast reduction with NaBH₄ (see Figure S1 in the SI), were used as initial seeds. Considering the pH-dependent redox potential of ascorbic acid as well as the ionization degree of PAH, we studied the influence of the pH on the overgrowth of the Au seeds. The nanoparticle growth was investigated at different pHs, ranging from 2.5 to 7.3 while keeping constant the number of seeds (53.3 pM in terms of NPs concentration), gold salt precursor and ascorbic acid. The Vis-NIR analysis of the resulting colloids revealed that at pHs ranging from 2.5 and 5 the total reduction of the Au salt occurs while pH above 5 inhibited the reduction of the Au precursor and even compromised the colloidal stability (Figure S2 in SI). Moreover, in the pH range 2.5-5, the optical properties of the resulting nanoparticles are strongly influenced by the pH and, as expected, this difference in the optical properties is reflected in the morphology of the particles (Figure 1A). While at pH 2.5 the resulting Au colloids show a
relatively narrow localized surface plasmon resonance (LSPR) band at ca. 557 nm being the particles fairly spherical (Figure 1B), the gradual increase of pH from 3.9 to 4.8 gives rise to a red-shift of the LSPR as well as the appearance of a new and less intense plasmon mode at lower wavelengths. Thus at pH 4.1, the AuNPs resemble a popcorn with a core of about 50 nm and branch lengths of 10-15 nm (Figure 1B,C). Significantly, as the pH increases to 4.8 the length of these branches increased while the core slightly decreased (Figure 1C-D). This is in agreement with previous reports where the two dipolar resonances were assigned to LSPR modes localized at either the central core of the NPs (located around ca. 520 nm) or the tips/branches of the NPs (being its position depending on its length and sharpness). On the other hand, The highly positive surface potential ($\zeta = +46.1 \text{ mV}$) reveals that the resulting NPs are stabilized by PAH.
Figure 1. (A) Vis-NIR spectra of the AuNPs synthesized in the presence of PAH at different pHs (2.5, 3.9, 4.1, 4.6 and 4.8) upon injection of gold seeds (final NP concentration: 53.3 pM). (B-D) Representative TEM images of AuNPs obtained at pH 2.5 (B), 4.1 (C) and 4.8 (D).

Next, we evaluated the influence of the amount of seed on the growth process. Figure 2 shows the vis-NIR spectra of the AuNPs obtained at pH 4.1 and varying the amount of seed added from 106.6 pM to 8.9 pM. As shown in Figure 2A, as the amount of seeds decreases the LSPR band of the resulting nanoparticles red-shifts evidencing a second band at lower wavelengths, in such a way that it can be fine-tuned from ca. 560 nm to 1260 nm. These differences in the optical response are reflected in their morphology (Figures 2 and S3-S7 in
SI). For the highest amount of seeds (106.6 pM), the particles are fairly monodisperse with a bumpy morphology and an average size of $49 \pm 6$ nm (Figures 2B and S3). As the amount of seed decreased from 106.6 pM to 8.9 pM, the initial bumps evolved into larger branches (Figures 2D-F and S3-S7 in the SI) producing a red-shift of the main LSPR. This evolution in the morphology of the AuNPs is also accompanied by an increase in the mean overall size from 49 nm to 151 nm as determined by TEM analysis. Considering the remarkable effect of the solution pH in the morphology of the Au nanoparticles obtained with the addition of a constant amount of seed (53.31 pM, Figure 1), the study was extended to other seeds amounts. The results obtained with 26.7 pM and 8.9 pM at pHs 2.5 and 4.1 reveal the strong effect of the pH in the growth of NPs regardless of the amount of seed added (see Figures S8 and S9 in the supporting information).

**Figure 2.** (A) Normalized Vis-NIR spectra of branched AuNPs obtained using different amounts of Au seeds. The final Au NPs concentrations were: 8.9 pM, 13.3 pM, 17.8 pM, 26.7 pM, 35.4 pM, 53.3 pM, 71.1 pM, 106.6
Representative TEM images of AuNPs obtained using 106.6 pM (B), 53.3 pM (C), 35.4 pM (D), 26.7 pM (E) and 8.9 pM (F) of Au seeds.

To investigate the NPs formation, the time evolution of the optical properties during the AuNP growth (for 53.3 pM Au seeds) was analyzed at pH 2.5 and 4.1. At pH 2.5 the reaction is complete in less than 3 minutes since the well-defined LSPR centered at ca. 555 nm (t = 3 min) did not undergo noticeable changes at longer times (see Figure S10A). On the other hand, at pH 4.1 (see Figure S10B) the kinetic study revealed that the reaction proceeds a bit slower than at 2.5 and two different stages could be distinguished. Thus, there is a fast initial stage where the reduction of the gold salt takes place in five minutes, monitored through the extinction at 400 nm, giving rise to Au nanoparticles with a broad and poorly defined LSRP band (see red spectrum in Figure S10B). Besides there is a second stage, from 5 minutes to ca. 240 minutes, where no further reduction of gold salt is produced and the morphological evolution of the nanoparticles takes place as indicated by the blue-shift, sharpening and increase in the intensity of the main LSPR band (see Figure S10B). It should be pointed out that these optical changes were also observed for Au NPs growth from 26.7 pM Au seeds (see Figure S10C in the SI).

To investigate more in-depth the particles growth, aliquots were withdrawn at different reaction times during the formation of Au NPs and analyzed by TEM and Vis-NIR spectroscopy after inhibiting the growth process via the addition of thiolated PEG (Figure 3A and Figure S11 in the SI). As shown in Figure 3A and Figure S11 for 53.3 pM Au seeds and pH 4.1, the gold salt reduction is very fast, thus ~5 seconds after the seed addition close to 70% of the gold salt is reduced (estimated from the extinction at 400 nm) and the resulting NPs exhibit an LSPR band located at ca. 610 nm. TEM analysis revealed that
these particles present small and multiple bumps at their surface and an overall average diameter of ca. 55 nm (Figure 3B and S12). From 15 seconds to 5 minutes the initial bumps grow in random directions leading to an increase in the number and length of the branches (see Figure 3C and Figure S13A-D in the SI). Eventually, after 5 minutes the AuNPs gradually evolve into a morphology with a lower degree of branching but accompanied by an increase in its curvature, as indicated by the narrowing an increase in the intensity of the main LSPR (Figure 3D and Figure S13E-H).

**Figure 3:** (A) Time-resolved vis-NIR spectra of the AuNP growth at pH 4.1 upon the addition of obtained Au seeds (53.3 pM in NP concentration). (B-D) Representative TEM images of the Au intermediates after arresting the growth process at the indicated times.
The morphology and structure of branched AuNPs obtained with 53.3 pM and 8.9 pM gold seeds were further investigated by high-resolution TEM (HRTEM) and high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM), Figure 4. The analysis of the AuNPs reveals that the branches show different crystallographic orientations with twin boundaries between them (see black arrows in Figure 4D and 4J). Interestingly, the HAADF analysis reveals small regions with slightly different contrast mostly seen near lattice defects (see red arrows in Figure 4B,C,H and I), which could indicate the presence of holes in the internal structure of the NP. Besides, we performed 3D structural analysis through electron tomography to obtain further information regarding the morphology as well as to confirm the presence of holes in its structure. Figure 5 and S14 shows representative electron tomography reconstruction of different AuNPs obtained at pH 4.1 using 53.3 pM or 8.9 pM Au seeds, where their multiple branched morphology is confirmed. Additionally, the orthoslices through the reconstructions show the presence of holes within the structure (Figure 5C and D and S14), which are more evident in the larger particles (Figure S14). Animated visualizations of the obtained reconstructions are provided as Supporting Information for both types of AuNPs (see Movies S1 to S4 in the Supporting Information).

with 8.9 pM Au seeds (E, F). Different orthoslices through the reconstruction revealing the location of holes and defects in the Au nanostructures of NPs obtained at pH 4.1 and with 53.3 pM Au seeds (C, D) and 8.9 pM Au seeds (G, H) (Scale bar correspond with 50 nm in both cases)

The above results show a remarkable influence of the pH on the final morphology of the particles. Thus, working in a pH range of 2.5 - 5 the particles show a well-defined morphology ranging from spherical to highly branched NPs. To summarize, to analyze the effect of pH in the particles growth, we need to take into consideration the following:

i) The pH influences the ionization degree of the PAH being its reported pKa values in the pH range 8-9. In fact, as weak cationic polyelectrolyte bearing primary amines, PAH can show from extended coil to segmental collapse conformational changes upon tuning its charge with the pH. On the other hand, the pH and the presence of Cl⁻ determine the speciation of gold(III) species in the solution. Thus, while at pH range 2.5 just AuCl₄⁻ is present in the reaction medium, between 3 and 6 two species, AuCl₄⁻ and AuCl₃(OH)⁻, coexist. Besides, although the most abundant species is the AuCl₄⁻, the amount AuCl₃(OH)⁻ gradually increases with the pH.

ii) At the studied pH range (2.5 - 5), the PAH is highly charged, therefore we expect the formation of ion pairs between the protonated amine group of PAH and the gold salt precursor (AuCl₄⁻ or AuCl₃(OH)⁻) which can also lead to the formation of colloidal aggregates. Interestingly, the formation of these ion pairs shifts their redox potential to more negative values, similar to what has been reported for quaternary ammonium salts.

Based on the previous consideration, PAH-Au(III) mixtures at different pHs (namely 2.5, 4.1 and 4.8) were analyzed by dynamic light scattering (DLS). Interestingly, the analysis indicates the presence of colloidal aggregates independently of the pH with average sizes.
ranging from 26 nm to 143 nm from pH 2.5 to pH 4.8, respectively (see Figure S15 and Table S1 in the SI). Therefore, we propose that the PAH-Au(III) mixtures, corresponding to a PAH monomer:AuCl₄⁻ ratio of 3.6, led to a decrease of the electrostatic repulsions between adjacent protonated amine units due to ion-pair formation and being responsible for the colloidal polymer aggregate formation.

iii) The formation of the ion-pair is corroborated by the absence of nucleation after adding the AA due to shifting the redox potential of the gold precursor to more negative values. The chemical reduction of the Au species is just triggered by the addition of gold seeds. Besides, the average size of the obtained particles can be modulated by the amount of seed solution added. This is in full agreement with previous reports on the seeded growth of Au NPs. At a fixed pH, the size control is also accompanied by a tunability of the optical properties of the NPs from the visible to the NIR region (Figure 2), which is associated with their morphology, and particularly with the lengths and number of branches.

iv) The influence of the pH in the final morphology of the particles could be also ascribed in part to the pH-dependent AuCl₄⁻ : AuCl₃(OH)⁻ ratio present in the reaction medium. Moreover, the kinetics of the process could be considered as fast with the gold salt reduction taking place in the first 3 minutes. Interestingly, once the gold salt is reduced a reshaping process occurs where the branched morphology is smoothed resulting in the narrowing and intensification of the LSRP band. Thus, the formation of size-dependent PAH-AuCl₄⁻ aggregates as demonstrated by DLS may be responsible for the branched morphology of overgrown particles and the appearance of internal voids in the particles for highly branched nanoparticles (see Figure 4).

Next, we evaluated the sensing capabilities of this new type of branched AuNPs studying the shift in the LSPR band induced by a change in the local refractive index around
Thus, the refractive index sensitivity (RIS), defined as the shift in the LSPR band with the variation of the refractive index of the medium (Δλ/Δn), were measured by varying the refractive index of the solution using different water-glycerol mixtures (see Figure 6A and further details in Figures S16 and S17 in SI). Three different types of branched NPs with LSPR bands located at 538 nm, 600 nm and 709 nm were studied (see Figure S16). All the samples show a reasonably good linear dependence of the LSPR shift with the refractive index (see Figure S17). The RIS determined from the linear fit were 95, 163 and 305 nm/RIU for the AuNPs with the LSPR centered at ca. 538 nm, 600 nm and 709 nm, respectively. As expected, the branched AuNPs with longer LSPR presented higher sensitivity and with values similar consistent with studies on other anisotropic NPs. 

Interestingly, the reliability of LSPR sensing, and therefore the RIS, can be improved by analyzing the curvature of the LSPR band. The curvature of the LSPR band is characterized by the peak maximum and two inflections points. The two inflection points can be easily obtained since they appear as local maxima/minima in the first-order derivative and have a 0 value in the second-order derivative spectrum (see red circles in Figure 6B), with the inflection point at the red side of the LSPR band showing a higher RIS than that obtained by the peak maximum. Figure 6C shows the RIS measured for the three types of branched Au NPs at the peak maximum and the inflection point at longer wavelengths. In the three cases, the inflection point presents a better RIS performance, with an improvement ranging from 11.5 % to 24.5 % which is similar to that reported for other Au nanoparticles.
Figure 6. (A) Extinction spectra of branched AuNPs dispersed in different water-glycerol mixtures as indicated with the LSPR centered at 709 nm in water. (B) Representative extinction (top), first derivative (middle), and second derivative (bottom) spectra of branched AuNPs. The dashed blue lines are a guide for the eye. The red circles indicate the LSPR band maximum, indicated by the 0 value of the first-order derivative spectrum, and the inflection point at longer wavelengths of the extinction spectrum, which shows a 0 value in the second-order derivative spectrum. (C) Refractive index sensitivities were obtained from the LSPR peak maximum and the inflection point at longer wavelengths for the three types of branched NPs studied.

Finally, one of the key issues for the applicability of the Au nanoparticles is the ease of surface functionalization. To demonstrate that, we carried out as a proof of concept the functionalization of the as-synthesized AuNPs with polyacrylic acid-co-maleic acid
(PAcMA) via NHS/EDC chemistry. Thus the carboxylic acid functional groups from PAcMA will form an amide bond with the amine groups from PAH.\textsuperscript{42,43} After the functionalization the characteristic LSRP band of Au branched NPs exhibited a slight red-shift (\textit{ca.} 10 nm) that can be explained by changes in the dielectric medium surrounding the NPs after functionalization (see \textbf{Figure S18} in the SI).\textsuperscript{44} Additionally, the $\zeta$-potential of the Au NPs, initially highly positive, became highly negative (-48.4 mW) due to the carboxylic moieties of the PAcMA polymer. Moreover, the presence of PAcMA on the NPs surface was also demonstrated by FTIR spectroscopy (see \textbf{Figure S19} in the SI). Interestingly, the PAcMA functionalization confer a high stability to the particles even in phosphate buffer saline (PBS, pH = 7.6, [Phosphate] = 100 mM, [NaCl] = 200 mM). The surface modification with PAcMA through electrostatic interactions led to limited stability in PBS as demonstrated by the overall increase in the intensity of the extinction spectrum together with the broadening of the LSPR band (see \textbf{Figure S20} in the SI).

\textbf{Conclusions}

We have developed a seed-mediated synthesis of branched AuNPs in the presence of PAH that offers tight control over the optical properties in the Vis-NIR (560-1260 nm) region. Relevant aspects of this synthesis are the possibility of taking advantage of the PAH-Au(III) interaction at different pH to drive the growth of NPs over small pre-synthesized gold seeds to control the size and branching morphology of AuNPs formed, thus covering a wide wavelength range in visible and near-infrared. Advanced electron microscopy techniques demonstrated the polycrystalline nature of the NPs and facilitated a better understanding of branched morphology. The mechanism of nanostructure formation was explored. A Kinetically controlled growth at early stages, probably due to preferential growth of the twin
boundaries of spherical seeds with a multi-twinned crystallographic structure is proposed. Additionally, the LSPR sensing capabilities of this new type of particles were evaluated by measuring the refractive index sensitivity by the inflection point. Furthermore, the versatility of the PAH chemistry allowed the easy functionalization of the synthesized NPs. We hope that the present work will drive the development of new anisotropic nanoparticles tailored for particular applications and suggest new future directions to explore in branched AuNPs synthesis using polyamines.

**Experimental section**

**Materials**

Gold(III) chloride trihydrate (HAuCl₃·3H₂O, 99.9%), trisodium citrate dihydrate (C₆H₅Na₃O₇·2H₂O, ≥ 99.5%), sodium borohydride (NaBH₄, ReagentPlus® 99%), L-ascorbic acid (C₆H₈O₆, BioXtra ≥ 99.0% crystalline), poly(allylamine hydrochloride) ([CH₂CH(CH₂NH₂·HCl])ₙ, average Mw 50,000 (GPC vs. PEG std.)), sodium hydroxide (NaOH, BioXtra ≥ 98%, pellets, anhydrous) hydrochloric acid (HCl, ACS reagent, 37%), N-(3-dimethylaminopropyl)-N′-ethylcarbodiimide hydrochloride (EDC), poly(acrylic acid-co-maleic acid) solution (PAcMA, average Mw 3,000, 50 wt. % in H₂O) were obtained from Sigma-Aldrich. N-Hydroxysuccinimide (NHS, 98+%)) was obtained from Alfa Aesar. All reagents were used as received without further purification. Ultrapure water (type I) was used for the preparation of all the water-based solutions. The glassware was cleaned with aqua regia prior to the experiments.

**Methods**

*Synthesis of gold seeds.* The synthesis of the gold seeds was based on a previous report with a few modifications.²⁴ Briefly, 20 mL of an aqueous solution containing 0.125 mM HAuCl₄ and 0.25 mM trisodium citrate was prepared in a round-bottomed flask at RT. Under vigorous stirring, 300 µL of an ice-cold freshly
Prepared 0.01 M NaBH₄ solution was rapidly injected. Vigorous stirring was maintained for 15 more seconds and then slowed down for 15 min at RT. The seed solution was heated 60 minutes at 40 °C with slow magnetic stirring and then cooled with continued stirring to ensure the removal of excess NaBH₄ before use. The seed solution was diluted to a final concentration of 0.1 mM in Au metal for the NP growth experiments.

*Preparation of poly(allylamine hydrochloride) solution.* 1 mg mL⁻¹ PAH solution was prepared in water (5 mM HCl). After vigorous stirring, the PAH solution was left undisturbed for a minimum of 3 days for complete solubilization of the polymer.⁴⁵

*Synthesis of branched AuNPs.* In a round bottom reaction flask containing a certain volume of Milli-Q water (ca. 17 mL), 2 mL of PAH (1 mg mL⁻¹) and 0.3 mL of HAuCl₄ (20 mM) were added under vigorous magnetic stirring. After that, the pH was adjusted with either NaOH or HCl (0.2 M) solution. Thus, to adjust the pH to 2.5, 0.2 mL of HCl (0.2 M) was added to the aqueous solution. Instead, for pHs between 3.5 and 7.3, volumes between 0.1 and 0.3 mL of NaOH (0.2 M) were added. After 5 minutes of vigorous stirring, 0.5 mL of AA (20 mM) was added and subsequently a certain amount of gold seeds ([Au⁰] = 0.1 mM). The total volume was 20 mL regardless of the amount of seed added. Experiments with final NP concentrations of Au seeds of 8.9 pM, 13.3 pM, 17.8 pM, 26.7 pM, 35.4 pM, 53.3 pM, 71.1 pM, 106.6 pM were carried out. The reactions were kept for 4 h at 22 °C under vigorous stirring. Then the NPs were purified by centrifugation (between 1500 and 3500 rpm, depending on the size) re-suspended in miliQ water.

*Arresting the reaction.* To monitor the progress of the reaction carried out at pH 4.1 and 53.3 pM of seeds, 3 mL aliquots were extracted from the reaction at various times and added to 2 mL of aqueous PEG-SH solution (1 mg mL⁻¹) and then vigorously stirred. After 30 min. the NPs were isolated by centrifugation at 9000 rpm, then resuspended in 1.5 mL of Milli-Q water for transmission electron microscopy (TEM) and Vis-NIR spectroscopy analysis.

*Functionalization of AuNPs with poly(acrylic acid-co-maleic acid).* PAcMA was activated with EDC/NHS before adding it to the AuNPs. Briefly, to 5 mL of an aqueous solution containing 6 µL (50 wt. % in H₂O) of PAcMA, 5 mL of 30 mM EDC and 5 mL of 30 mM NHS were added. The reaction was maintained under ultrasound for 15 minutes then vigorous magnetic stirring for 2 h. The activated polymer solution was dripped
onto the NP reaction, which was vigorously stirred for 4 h. (Note: During the course of reaction, the NPs coalesced even under magnetic stirring, so the NPs were re-suspended using ultrasound to ensure a homogeneous solution) Finally, the AuNPs were washed repeatedly with PBS (pH = 7.4) and water.

**Characterization**

The extinction spectra were recorded using a JASCO 770 UV–Vis-NIR spectrophotometer provided by the PROTEOMASS-BIOSCOPE facility (Caparica, Portugal). All spectra were recorded using a HELMA 1 cm light path quartz cell. Dynamic light scattering (DLS) and ζ-potential analysis were carried out in a Malvern ZS instrument at 22 ºC in standard 1 mL polystyrene cuvettes provided by the PROTEOMASS-BIOSCOPE facility (Caparica, Portugal). DLS measurements were obtained with 180 sec of equilibration time. Fourier transform infrared (FT-IR) analysis was performed using a Bruker Tensor 27 instrument in KBr or NaCl discs and with a resolution of 4 cm⁻¹. Low magnification transmission electron microscopy (TEM) images were obtained using a JEOL JEM 1010 TEM microscope, working at 100 kV. A JEOL JEM 2010F field-emission gun TEM working at 200 kV was used to obtain HRTEM images. Particle size and mean size distribution were calculated from TEM micrographs using the ImageJ package. High angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) images and electron tomography series were acquired using a Probe-Corrected FEI Titan G2 80-200 kV ChemiSTEM. A dual-axis tomography with ±70° was performed in both axes to minimize the missing wedge. Gold fiducials of 10 nm in size were deposited on the grids before depositing the AuNPs to allow for highly accurate tracking and reconstruction, and the acquisition was carried out with an 8 mrad convergence angle.

Author Contributions

S.N., C.F-L, J.F-L and A.F-L performed the experiments, data analysis, the calculations, and wrote the first manuscript draft. C. F-L and J. F-L perform Low-Resolution TEM analysis. J. P-J, I. P-S and J. L. C-M, C. L, helped with useful tips regarding the experimental data analysis. A. P. L-G and O. S. provided the HRTEM, HAADF STEM and Tomography analysis. J. F-L, C.L, J. P. J, I. P-S and J. L C-M. obtained the funding for the project. All authors contributed to writing and correction of final draft, given approval for the final version of the manuscript.

‡These authors contributed equally.

Funding Sources

The authors acknowledge the financial support by the Associate Laboratory Research Unit for Green Chemistry-Clean Processes and Technologies-LAQV which is financed by national funds from FCT/MEC (UID/QUI/50006/2013) and co-financed by the ERDF under the PT2020 Partnership Agreement (POCI-01-0145-FEDER-007265), as well as the PROTEOMASS Scientific Society General Funds (Portugal) for funding support. S.N.; J.F.-L., A.F.-L.; C.L. and J.L.C.-M. thank the FCT-MEC for the research grant SiSi4Bacter (PTDC/QUI-COL/1517/2020). I. P.-S. and J.P.-J. acknowledge financial support from Spanish MINECO grant PID2019-108954RB-I00.

Acknowledgments

J.F.-L. thanks the FCT-UNL for the DL57/2016 Assistant Researcher Contract. S.N. thanks the FCT-MEC Portugal for her doctoral grant associated with the Chemistry PhD program (SFRH/BD/144618/2019). A.F.L. thanks the FCT-UNL for the DL57/2021 Assistant Researcher Contract under the grant PTDC/QUI-COL/1517/2020, and C. F.-L. acknowledges Xunta de Galicia for a predoctoral scholarship (Programa de axudas á etapa predoutoral).

(B-C) Time evolution of extinction spectra of AuNP growth at pH 4.1 upon injection of 53.3 pM (B) or 26.7 pM (C) Au seeds. The spectra were recorded between 3 minutes (red line) and 240 minutes (blue line) of reaction.
Figure S11. Vis-NIR spectra of Au colloids withdraw at different reaction time as indicated (see further discussion below and experimental section for details).

The growth of the AuNPs was arrested at different reaction times by adding PEG-SH in excess in the reaction medium (see experimental part). To remove the excess of thiolated molecules and unreacted gold salt, the intermediates were washed by centrifugation and analyzed by Vis-NIR spectroscopy and electron microscopy. Interestingly, the optical properties of the different intermediates before and after the arresting/purification step are similar (Figure 3A and S11) indicating that the morphology of the particles was preserved. Similar results were also observed when comparing the time-course of the arrested reaction intermediates with that of the in situ reaction shown in Figure S10B.
Figure S12: TEM images of arrested intermediates. PEG-SH injected at 5 seconds of reaction.
Figure S13. TEM images of arrested intermediates. PEG-SH injected at 15 second (A) and 5, 30 and 90 minutes (B, C and D respectively).

Figure S14. (A and B) 3D STEM tomographic reconstruction of two different nanoparticles along two different viewing directions of the Au nanoparticles. (C and D) Two different ortho slices from A (C) and B (D) through the reconstruction revealing the location of holes and defects in the Au nanostructures (Au nanoparticle obtained at pH 4.1 and with 8.9 pM Au seeds).
Figure S15. Dynamic light scattering (DLS) analysis of PAH-Au(III) at pH 2.5 (A), 3(B), 4(C) and 4.8 (D). The data represent the mean of 5 consecutive runs performed at 22°C and are referred to distribution by intensity.)
Figure S16. (A-C) Extinction spectra of branched AuNPs dispersed in different water-glycerol mixtures, as indicated, with the LSPR centered at 530 nm, 600 nm and 709 nm respectively. (D-F). First-order derivates of the AuNPs dispersed in different water-glycerol mixtures with the LSPR centered at 530 nm, 600 nm and 709 nm respectively. (G-I) Second-order derivates of the AuNPs dispersed in different water-glycerol with the LSPR centered at 530 nm, 600 nm and 709 nm respectively.

The refractive index of the water-glycerol mixtures was calculated through the Lorentz-Lorentz equation (see SI, Figure SX), as follows:

\[
\frac{n_{wg}^2 - 1}{n_{wg}^2 + 2} = \varphi_w \frac{n_w^2 - 1}{n_w^2 + 2} + \varphi_g \frac{n_g^2 - 1}{n_g^2 + 2}
\]

Where \( n_{wg} \) is the refractive index of the mixture, \( n_w \) (1.33) and \( n_g \) (1.47) are the refractive index of the water and glycerol, respectively, and \( \varphi_w \) and \( \varphi_g \) are their corresponding volume fractions.
Figure S17. Inflection point method for three branched AuNPs dispersed in different water-glycerol mixtures, as indicated, with the LSPR centered at 530 nm, 600 nm and 709 nm respectively. (A, C, D) 1st IF, maximum LSPR position and 2nd IF plotted against the different local refractive indexes for AuNPs with the LSPR centered at 530 nm, 600 nm and 709 nm respectively. (B, D, F) Sensitivity of local refractive index media on peak shifts 1st IF, maximum LSPR position and 2nd IF for AuNPs with the LSPR centered at 530 nm, 600 nm and 709 nm respectively.
Figure 18. (A) Normalized Vis-NIR spectra and (B) z-potential of AuNPs@PAH and post-functionalized with PAcMA (denoted as AuNPs@COOH). (C-D) TEM images of AuNPs@COOH.
The FTIR spectrum of pure PAcMA shows different characteristic signals: at 3387 and 2950 cm\(^{-1}\) assigned to the O-H and C-H stretching, respectively, at 1703 and 1635 cm\(^{-1}\) assigned to the COOH stretching and at 1443 and 1408 cm\(^{-1}\) attributed to the C=O stretching and O-H bending.\(^{[4]}\) On the other hand, the FTIR spectrum of the AuNPs@PAH@PAcMA NPs shows the characteristic signals that could be assigned to the carboxylic moieties (COOH stretching and at 1443 and 1408 cm\(^{-1}\)) as well as the band at 1560 cm\(^{-1}\) that could be assigned to the amide resulting of the amidation between PAH and PAcMA.\(^{[5]}\)
